1. Introduction

This international consensus statement is the collaborative effort of three medical societies representing electrophysiology in North America, Europe, and Asian-Pacific area: the Heart Rhythm Society (HRS), the European Heart Rhythm Association (EHRA), and the Asia Pacific Heart Rhythm Society. The objective of the consensus document is to provide clinical guidance for diagnosis, risk stratification, and management of patients affected by inherited primary arrhythmia syndromes. It summarizes the opinion of the international writing group members based on their own experience and on a general review of the literature with respect to the clinical data on patients affected by channelopathies.

This document does not address the indications of genetic testing in patients affected by inherited arrhythmias and their family members. Diagnostic, prognostic, and therapeutic implications of the results of genetic testing are also not included in this document because this topic has been covered by a recent publication1 coauthored by some of the contributors of this consensus document, and it remains the reference text on this topic. Guidance for the evaluation of patients with idiopathic ventricular fibrillation, sudden arrhythmic death syndrome, and sudden unexplained death in infancy, which includes genetic testing, are provided as these topics were not covered in the previous consensus statement.

Developing guidance for genetic diseases requires adaptation of the methodology adopted to prepare guidelines for clinical
practice. Documents produced by other medical societies have acknowledged the need to define the criteria used to rank the strength of recommendation for genetic diseases.2

The most obvious difference encountered for inherited diseases is that randomized and/or blinded studies do not exist in this field. Therefore, most of the available data derive from registries that have followed patients and recorded outcome information. As a consequence, all consensus recommendations are level of evidence C (i.e., based on experts’ opinions).

The consensus recommendations in this document use the commonly used Class I, IIa, IIb, and III classification and the corresponding language: “is recommended” for Class I consensus recommendation; “can be useful” for a Class IIa consensus recommendation; “may be considered” to signify a Class IIb consensus recommendation; “should not” or “is not recommended” for a Class III consensus recommendation (failure to provide any additional benefit and may be harmful).

Definitions of special terms used in the document
The terms used in the consensus document are defined as follows:

- Syncope: In the context of inherited arrhythmogenic disorders, the occurrence of “syncope” is an important indicator of arrhythmic risk. Although there is no definition to differentiate a syncopal episode caused by ventricular arrhythmias from an otherwise unexplained syncope, in the context of this document, the term “syncope” implies the exclusion of events that are likely due to vasovagal events such as those occurring during abrupt postural changes, exposure to heat and dehydration, and emotional reactions to events such as blood drawing. We refer to the guidelines of ESC and AHA/ACCF for the differential diagnoses of syncope.3,4

- Symptomatic individuals: The term “symptomatic” refers to individuals who have experienced ventricular arrhythmias (usually ventricular tachycardia or resuscitated ventricular fibrillation) or syncopal episodes (see definition above). The presence of symptoms is, in some of the channelopathies, an independent predictor of cardiac arrest at follow-up.

- Arrhythmic events: The term refers to the occurrence of symptomatic or asymptomatic sustained or nonsustained spontaneous ventricular tachycardia or unexplained syncope/resuscitated cardiac arrest.

- Concealed mutation-positive patients: This term is used to refer to individuals without clinical symptoms or phenotype of a channelopathy who carry the genetic defect present in clinically affected members of the family.

Methodological aspects and instructions for the consultation of the document
When considering the guidance from this document, it is important to remember that there are no absolutes governing many clinical situations. The final judgment regarding care of a particular patient must be made by the health-care provider and the patient in light of all relevant circumstances. Recommendations are based on the consensus of the writing group following the Heart Rhythm Society’s established consensus process. It is recognized that consensus does not mean unanimous agreement among all writing group members. We identified the aspects of patients’ care for which a true consensus could be found. Surveys of the entire writing group were used. The authors received an agreement that was greater than or equal to 84% on all recommendations; most recommendations received agreement of 94% or higher.

This statement is directed to all health-care professionals who are involved in the management of (1) individuals who survived a cardiac arrest at a young age (usually defined as <40 years) in the absence of a clinical diagnosis of cardiac disease, despite extensive clinical assessment; (2) family members of individuals who died suddenly at young age with a negative autopsy; (3) in patients and family members in whom the diagnosis of a channelopathy is clinically possible, likely, or established; and (4) young patients with unexplained syncope.

All members of this document writing group provided disclosure statements of all relationships that might present real or perceived conflicts of interest. Disclosures for all members of the writing group are published in Appendix A.

2. Long QT Syndrome (LQTS)

Expert Consensus Recommendations on LQTS Diagnosis

1. LQTS is diagnosed:
   a. In the presence of an LQTS risk score ≥3.5 in the absence of a secondary cause for QT prolongation and/or
   b. In the presence of an unequivocally pathogenic mutation in one of the LQTS genes or
   c. In the presence of a corrected QT interval for heart rate using Bazett’s formula (QTc) ≥500 ms in repeated 12-lead electrocardiogram (ECG) and in the absence of a secondary cause for QT prolongation.

2. LQTS can be diagnosed in the presence of a QTc between 480 and 499 ms in repeated 12-lead ECGs in a patient with unexplained syncope in the absence of a secondary cause for QT prolongation and in the absence of a pathogenic mutation.

Expert Consensus Recommendations on LQTS Therapeutic Interventions

Class I
1. The following lifestyle changes are recommended in all patients with a diagnosis of LQTS:
   a. Avoidance of QT-prolonging drugs (www.qtdrugs.org)
   b. Identification and correction of electrolyte abnormalities that may occur during diarrhea, vomiting, metabolic conditions, or imbalanced diets for weight loss.
2. Beta-blockers are recommended in patients with a diagnosis of LQTS who are: a. Asymptomatic with QTc $\geq 470$ ms and/or b. Symptomatic for syncope or documented ventricular tachycardia/ventricular fibrillation (VT/VF).

3. Left cardiac sympathetic denervation (LCSD) is recommended in high-risk patients with a diagnosis of LQTS in whom: a. Implantable cardioverter-defibrillator (ICD) therapy is contraindicated or refused and/or b. Beta-blockers are either not effective in preventing syncope/arrhythmias, not tolerated, not accepted or contraindicated.

4. ICD implantation is recommended in patients with a diagnosis of LQTS who are survivors of a cardiac arrest.

5. All LQTS patients who wish to engage in competitive sports should be referred to a clinical expert for the evaluation of risk.

Class IIa 6. Beta-blockers can be useful in patients with a diagnosis of LQTS who are asymptomatic with QTc $\leq 470$ ms.

7. ICD implantation can be useful in patients with a diagnosis of LQTS who experience recurrent syncopal events while on beta-blocker therapy.

8. LCSD can be useful in patients with a diagnosis of LQTS who experience breakthrough events while on therapy with beta-blockers/ICD.

9. Sodium channel blockers can be useful, as add-on therapy, for LQT3 patients with a QTc > 500 ms who shorten their QTc by > 40 ms following an acute oral drug test with one of these compounds.

Class III 10. Except under special circumstances, ICD implantation is not indicated in asymptomatic LQTS patients who have not been tried on beta-blocker therapy.

Epidemiology
Patients affected by the LQTS have been identified all over the world and in all ethnic groups. A possible exception is represented by a paucity of cases identified among black Africans and among African-Americans. Among Caucasians, the prevalence of LQTS has been 1:2000 apparently healthy live births.\(^5\)

Clinical manifestations
The clinical manifestations of LQTS fall under two main categories: the arrhythmic events and the ECG aspects.

The arrhythmic events are due to runs of torsades de pointes VT, which, according to its duration, produces syncope and—when it deteriorates into VF—cardiac arrest or sudden death.

In ECG alterations, prolongation of the QT interval is the hallmark of LQTS but it is not always present. Ventricular repolarization is not only prolonged but often presents bizarre morphologic alterations, some of which tend to be gene-specific.\(^6\)

Diagnosis
The diagnosis of LQTS is mainly based on the measurement of the QTc. When using a prolonged QTc to diagnose LQTS, one must exclude secondary causes of QTc prolongation that can occur with drugs, acquired cardiac conditions, electrolyte imbalance, and unbalanced diets. A scoring system has been established, which takes into account the age of the patient, medical and family history, symptoms, and QTc and provides a probability of the diagnosis of LQTS.\(^7,8\)

Approximately 20%–25% of the patients with LQTS confirmed by the presence of an LQTS gene mutation may have a normal range QTc.\(^9,10\)

Risk stratification
Individuals at the extremes of the curve, those at very high or at very low risk, are easy to identify. For the larger group, in the gray area, risk stratification is difficult and can be fraught with errors in either direction. The Jervell and Lange-Nielsen syndrome\(^11\) and the extremely rare Timothy syndrome (LQT8)\(^12\) are highly malignant, manifest with major arrhythmic events, and respond poorly to therapies. Within the most common genetic groups, specific locations, types of mutations, and degree of mutation dysfunction are associated with different risks.

High risk is present whenever QTc > 500 ms\(^9,13\) and becomes extremely high whenever QTc > 600 ms. Patients with two unequivocally pathogenic variants and a QTc > 500 ms are also at high risk. The presence of overt T-wave alternans is a direct sign of electrical instability and calls for preventive measures. Patients who have syncope or cardiac arrest before age 7 have a higher probability of recurrence of arrhythmic events while on beta-blockers.\(^14\)

Patients who have syncope or cardiac arrest in the first year of life are at high risk for lethal events and may not be fully protected by the traditional therapies.\(^15,16\) Patients who suffer arrhythmic events despite being on full medical therapy are at higher risk.

Management
Lifestyle modifications such as avoidance of strenuous exercise and avoidance of drugs that prolong QT interval in all LQTS patients should be routine. Participation of LQTS patients in competitive sports is still a matter of debate among the experts. Specific therapies available for patients with LQTS and indications for their use are described below.

Beta-blockers
Beta-blockers are clinically indicated in LQTS, including those with a genetic diagnosis and normal QTc, unless there is a contraindication such as active asthma.\(^14,15\) Although
studies are not available to define the most effective dosage, full dosing for age and weight, if tolerated, is recommended. Abrupt discontinuation of beta-blockers should be avoided as this may increase the risk of exacerbation.

**ICD (Figure 1)**

ICD therapy is indicated in LQTS patients who are resuscitated from cardiac arrest.\(^{17}\) ICD is often favored in patients with LQTS-related syncope who also receive beta-blockers.\(^{18}\) Prophylactic ICD therapy should be considered in very high risk patients. ICD therapy has lifetime implications, complications are not infrequent, especially in the younger age group, and risk/benefit considerations should be carefully considered before initiating this invasive therapy.\(^{19,20}\)

We suggest that ICD therapy not be used as first-line therapy in an asymptomatic LQTS patient; beta-blockers remain the first-line therapy in LQTS patients. However, an ICD may be considered in those patients who are deemed to be at very high risk, especially those with a contraindication to beta-blocker therapy.

Whenever ICD therapy is chosen, thoughtful programming (in particular to prevent inappropriate shocks) is pertinent and usually requires a VF-only zone, with a cutoff rate greater than 220–240 bpm.

**LCSD**

This procedure is often effective in reducing the probability for arrhythmic events in high-risk patients, including those who are intolerant of or refractory to beta-blockers alone.\(^{21}\)

**3. Brugada Syndrome (BrS)**

**Expert Consensus Recommendations on BrS Diagnosis**

1. BrS is diagnosed in patients with ST-segment elevation with type I morphology ≥2 mm in ≥1 lead among the right precordial leads V\(_1\), V\(_2\) positioned in the 2nd, 3rd, or 4th intercostal space occurring either spontaneously or after provocative drug test with intravenous administration of Class I antiarrhythmic drugs.

2. BrS is diagnosed in patients with type 2 or type 3 ST-segment elevation in ≥1 lead among the right precordial leads V\(_1\), V\(_2\) positioned in the 2nd, 3rd, or 4th intercostal space when a provocative drug test with intravenous administration of Class I antiarrhythmic drugs induces a type I ECG morphology.

**Expert Consensus Recommendations on BrS Therapeutic Interventions**

**Class I**

1. The following lifestyle changes are recommended in all patients with diagnosis of BrS:
   a. Avoidance of drugs that may induce or aggravate ST-segment elevation in right precordial leads (e.g., Brugadadrugs.org)
   b. Avoidance of excessive alcohol intake
   c. Immediate treatment of fever with antipyretic drugs.

**Class IIa**

3. ICD implantation can be useful in patients with a spontaneous diagnostic type I ECG who have a history of syncope judged to be likely caused by ventricular arrhythmias.

4. Quinidine can be useful in patients with a diagnosis of BrS and history of arrhythmic storms defined as more than two episodes of VT/VF in 24 hours.

5. Quinidine can be useful in patients with a diagnosis of BrS who:
   a. Qualify for an ICD but present a contraindication to the ICD or refuse it and/or
   b. Have a history of documented supraventricular arrhythmias that require treatment.

6. Isoproterenol infusion can be useful in suppressing arrhythmic storms in BrS patients.

**Class IIb**

7. ICD implantation may be considered in patients with a diagnosis of BrS who develop VF during programmed electrical stimulation (inducible patients).

8. Quinidine may be considered in asymptomatic patients with a diagnosis of BrS with a spontaneous type I ECG.

9. Catheter ablation may be considered in patients with a diagnosis of BrS and history of arrhythmic storms or repeated appropriate ICD shocks.
Class III 10. ICD implantation is not indicated in asymptomatic BrS patients with a drug-induced type I ECG and on the basis of a family history of sudden cardiac death (SCD) alone.

**Epidemiology**
No precise data are available on the epidemiology of BrS. However, its prevalence is much higher in Asian and Southeast Asian countries, especially Thailand, The Philippines, and Japan, reaching 0.5–1 per 1000. BrS is 8–10 times more prevalent in men than in women.

**Genetic basis**
Inheritance of BrS occurs via an autosomal dominant mode of transmission. Twelve responsible genes have been reported so far. In all 12 genotypes, either a decrease in the inward sodium or calcium current or an increase in one of the outward potassium currents has been shown to be associated with the BrS phenotype.

**Clinical manifestations**
Symptoms associated with BrS include VF or aborted SCD (more often at night than during the day), syncope, nocturnal agonal respiration, palpitations, and chest discomfort. These symptoms often occur during rest or sleep, during a febrile state, or with vagotonic conditions, but rarely during exercise.

**Diagnosis**
BrS is definitively diagnosed when a type I ST-segment elevation is observed either spontaneously or after intravenous administration of a sodium channel blocking agent (ajmaline, flecainide, pilsicainde, or procainamide) in at least one right precordial lead (V₁ and V₂), which are placed in a standard or a superior position (up to the 2nd intercostal space).

**Prognosis and risk stratification**
Since the first reporting, the reported annual rate of events has decreased.

Several clinical variables have been demonstrated to predict a worse outcome in patients with BrS. The high risk of recurrence of cardiac arrest is seen among patients who have survived a first VF. These patients should be protected with an ICD, irrespective of the presence of other risk factors.

Most studies have concurrently agreed on the evidence that the presence of syncopal episodes in patients with a spontaneous type I ECG at baseline (without conditions known to unmask the signature sign, i.e., drugs and fever) have high risk of cardiac arrhythmic events at follow-up.

Among other risk stratification indicators, the presence of fragmented QRS and an effective refractory period below 200 ms have been recently proposed. Male sex has consistently been shown to be associated with more arrhythmic events.

Although large registries agree that electrophysiological study (EPS) inducibility is greatest among BrS patients with previous sudden death or syncope, there is no consensus on the value of the EPS in predicting outcome.

**Therapeutic options and recommendations for BrS patients**
**ICD (Figure 2)**
The only proven effective therapeutic strategy for the prevention of SCD in BrS patients is the ICD. It is important to remark that ICDs are not free from several disadvantages, especially in the group of patients who are active young individuals who will require multiple device replacements during their lifetime. Asymptomatic BrS patients do not qualify for an ICD as their risk for life-threatening events is very low.

**Pharmacological treatment in BrS**
Isoproterenol (which increases the L-type calcium current) has proved to be useful for the treatment of electrical storm in BrS, but controlled data on its therapeutic role are not available.

Quinidine, a Class Ia antiarrhythmic drug with transient outward potassium current and rapid delayed rectifier current blocker effects, has been shown to prevent the induction of VF and suppress spontaneous ventricular arrhythmias in a clinical setting.

![Figure 2](Image)
Consensus recommendations for ICDs in patients diagnosed with Brugada syndrome.
Radiofrequency catheter ablation in BrS
After the demonstration that VF events were triggered by ventricular ectopy of similar morphology, radiofrequency ablation of ventricular ectopy has been postulated as a therapeutic approach in BrS patients. Few anecdotal cases in high-risk BrS implanted with an ICD have shown no short-term recurrence of VF, syncope, or SCD.41–44 Nade-manee et al45 have presented the first series showing that electrical epicardial substrate ablation in the right ventricular outflow tract can prevent VF inducibility in a high-risk population.

4. Catecholaminergic Polymorphic Ventricular Tachycardia (CPVT)

**Expert Consensus Recommendations on CPVT Diagnosis**

1. CPVT is diagnosed in the presence of a structurally normal heart, normal ECG, and unexplained exercise or catecholamine-induced bidirectional VT or polymorphic ventricular premature beats (VPBs) or VT in an individual younger than 40 years.
2. CPVT is diagnosed in patients (index case or family member) who have a pathogenic mutation.
3. CPVT is diagnosed in family members of a CPVT index case with a normal heart who manifest exercise-induced premature ventricular contractions or bidirectional/polymorphic VT.
4. CPVT can be diagnosed in the presence of a structurally normal heart and coronary arteries, normal ECG, and unexplained exercise or catecholamine-induced bidirectional VT or polymorphic VPBs or VT in an individual older than 40 years.

**Expert Consensus Recommendations on CPVT Therapeutic Interventions**

Class I

1. The following lifestyle changes are recommended in all patients with a diagnosis of CPVT:
   a. Limit/avoid competitive sports
   b. Limit/avoid strenuous exercise
   c. Limit exposure to stressful environments.

2. Beta-blockers are recommended in all symptomatic patients with a diagnosis of CPVT.

3. ICD implantation is recommended in patients with a diagnosis of CPVT who experience cardiac arrest, recurrent syncope or polymorphic/bidirectional VT despite optimal medical management, and/or LCSD.

Class IIa

4. Flecainide can be a useful addition to beta-blockers in patients with a diagnosis of CPVT who experience recurrent syncope or polymorphic/bidirectional VT while on beta-blockers.

5. Beta-blockers can be useful in carriers of a pathogenic CPVT mutation without clinical manifestations of CPVT (concealed mutation-positive patients).

Class IIb

6. LCSD may be considered in patients with a diagnosis of CPVT who experience recurrent syncope or polymorphic/bidirectional VT/several appropriate ICD shocks while on beta-blockers and in patients who are intolerant or with contraindication to beta-blockers.

Class III

7. ICD as a stand-alone therapy is not indicated in an asymptomatic patient with a diagnosis of CPVT.

8. Programmed electrical stimulation is not indicated in CPVT patients.

Introduction

CPVT is a rare arrhythmogenic disorder characterized by adrenergic-induced bidirectional and polymorphic VT.46,47

Epidemiology

The prevalence of the disease could be as high as 0.1:1000. However, the number is a rough estimate and is not derived from a systematic assessment in the population.

Genetic variants

Two types of CPVT have been identified: an autosomal dominant form, resulting from mutations in the gene encoding the cardiac ryanodine receptor (RyR2) known as CPVT1; and a less common autosomal recessive form, resulting from mutations in the gene for cardiac calsequestrin (CASQ2) known as CPVT2. Altogether mutations in RyR2 and CASQ2 are found in only 60% of the CPVT patients, suggesting that other genes may be involved in CPVT. In addition, mutations in KCNJ2 (also causing ATS [LQTS7]), Ank2, TRDN, and CALM1 have been associated with CPVT.53-57

Clinical manifestations

The first clinical episode often manifests in the first or second decade of life and is usually prompted by physical activity or emotional stress.47,58,59 When the fainting episode is associated with seizure-like activity, it may be attributed to a neurologic diagnosis, thus causing delay in the diagnosis of CPVT. A family history of exercise-related syncope, seizure, or sudden death is reported in 30% of the patients and may help directing diagnosis toward CPVT.

Diagnosis

CPVT patients present a normal resting ECG occasionally with a lower than normal heart rate.47,60 When patients start exercising ventricular ectopy develops, increasing in complexity as the heart rate increases. Indeed, initially monomorphic VPBs appear and they may be followed by polymorphic VPBs and bidirectional or polymorphic VT.
Risk stratification

There are not many indicators of risk of adverse outcome in CPVT. The occurrence of cardiac arrest before diagnosis, but not the occurrence of syncope, is associated with a higher risk of arrhythmic episodes at follow-up. Similarly, diagnosis in childhood is a predictor of adverse outcome. After diagnosis, the lack of beta-blocker therapy and the use of beta-blockers other than nadolol are independent predictors for arrhythmic events. Also, the persistence of complex ectopy in exercise tests is a marker for worse outcome.

Management

Beta-blockers

The first-line therapeutic option for patients with CPVT is beta-blockers without intrinsic sympathomimetic activity combined with exercise restriction. Nadolol being a long-acting drug is preferred for prophylactic therapy and has been found to be clinically effective. The dosage used is usually high (1–2 mg/kg), with the necessity of a faultless compliance to the therapy. The annual rate of arrhythmic events on beta-blockers ranges between 11% per year and 3% per year (27% over 8 years). Larger groups of CPVT probands are needed to address the issue of beta-blocker efficacy in CPVT. As nadolol is not available in several countries, it may be suggested that other nonselective beta-blockers are equally effective (i.e., propranolol). Holter recordings and exercise tests should be repeated periodically to assure that the degree of sinus tachycardia that precedes the onset of arrhythmias is known so that in daily life it can be avoided as much as possible. Moreover, to prevent non-compliance-related SCD, it is crucial to alert the patients of the importance of adherence to therapy to preempt life-threatening events.

ICD

An ICD should be considered in CPVT patients who do not respond to an optimal medical management and when LCSD is not possible. All efforts should be made to ensure that patients with an ICD also have an optimal medical treatment. In patients who have experienced an aborted cardiac arrest before the initiation of therapy, beta-blockers or beta-blockers and flecainide should be started and ICD implanted.

Implantation of an ICD is a technical challenge in pediatric patients and problems such as inappropriate shocks, proarrhythmic effects of the ICD, and the need for a lifetime protection requiring multiple reinterventions should be addressed when the decision is taken. Painful shocks by ICD can increase the sympathetic tone and trigger further arrhythmias, leading to a malignant cycle of ICD shocks and even death. Because of this, the ICD should be programmed with long delays before shock delivery and high cutoff rates.

Verapamil

Verapamil has been shown to be beneficial in some CPVT patients by reducing the ventricular arrhythmia burden on top of beta-blocker therapy during a short-term follow-up period, though its long-term effect remains controversial.

Flecainide

Flecainide reduces significantly the ventricular arrhythmia burden in a limited number of CPVT patients. A larger study is required to fully elucidate the effect of the drug, but flecainide should now be regarded as the first addition to beta-blockers when control of arrhythmias seems incomplete.

LCSD

Small series have been published reporting significant results of LCSD on arrhythmic events. Although the short-term results seem encouraging, more data with a long-term follow-up are needed.

Catheter ablation

Catheter ablation of the bidirectional VPBs that trigger VF may become an adjunctive therapy in patients with refractory CPVT. However, the published experience is very limited and is therefore not discussed in the recommendation.

Evaluation of family members

Family screening (siblings and parents) by clinical evaluation and genetic testing (when a mutation has been detected) is mandatory to identify undiagnosed patients and asymptomatic carriers who are at risk of arrhythmic events and should be treated. It is suggested that genetically positive family members should receive beta-blockers even after a negative exercise test.

5. Short QT Syndrome (SQTS)

Expert Consensus Recommendations on SQTS Diagnosis

1. SQTS is diagnosed in the presence of a QTc ≤330 ms.
2. SQTS can be diagnosed in the presence of a QTc <360 ms and one or more of the following: a pathogenic mutation, family history of SQTS, family history of sudden death at age ≤40 years, and survival of a VT/VF episode in the absence of heart disease.

Expert Consensus Recommendations on SQTS Therapeutic Interventions

Class I 1. ICD implantation is recommended in symptomatic patients with a diagnosis of SQTS who:
   a. Are survivors of a cardiac arrest and/or
   b. Have documented spontaneous sustained VT with or without syncope.

Class IIb 2. ICD implantation may be considered in asymptomatic patients with a diagnosis of SQTS and a family history of SCD.
Epidemiology and genetic bases
One of the rarer cardiac channelopathies is the SQTS. Gussak et al. were the first to suggest an association with atrial fibrillation and VF (i.e., SCD). With more case reports halfway through the first decade of this century, this association became clearer, but more than 10 years after the first description, the number of patients reported is small, underlining the fact that the disease entity is indeed rare. Until now, DNA variants in 3 potassium channel genes—KCNH2, KCNQ1, and KCN2—have been described to associate with SQTS; interestingly, mutations in these three genes are also linked with three variants of LQTS: LQT1, LQT2, and LQT7, respectively.

Clinical diagnosis
The diagnosis of SQTS is still a matter of debate. A major point of discussion in the definition of diagnostic criteria is represented by the cutoff value at the lower end of the QTc that should be used to diagnose the disease. The QTc should be calculated avoiding tachycardia and bradycardia to prevent the use of Bazett’s formula at rates at which its correction is not linear and may lead to the underestimation or overestimation of QTc values.

This group has reached a consensus that a cutoff value of ≤330 ms should be used for the diagnosis.

Risk stratification and treatment
Therapeutic management using ICDs is undisputed in SQTS patients who have experienced sustained VT/VF episodes. Appropriate programming of the ICD is needed to prevent inappropriate ICD shocks from T-wave oversensing due to tall T waves. Quinidine seems to be an effective alternative due to its QT-prolonging action. Other drugs, including Class III drugs, such as sotalol, are not effective in prolonging the QTc in SQT1 patients, but may be effective in other subtypes.

The optimal strategy for the primary prevention of cardiac arrest in SQTS is not clear, given the lack of independent risk factors for cardiac arrest.

There are certainly no data to support the implantation of an ICD in asymptomatic patients with SQTS. An ICD might be considered in SQTS patients with a strong family history of SCD and evidence for abbreviated QTc in at least some of the victims.

6. Early Repolarization (ER)

Expert Consensus Recommendations on ER Diagnosis

1. ER syndrome is diagnosed in the presence of J-point elevation ≥1 mm in ≥2 contiguous inferior and/or lateral leads of a standard 12-lead ECG in a patient resuscitated from otherwise unexplained VF/polymorphic VT.
2. ER syndrome can be diagnosed in a SCD victim with a negative autopsy and medical chart review, with a previous ECG demonstrating J-point elevation ≥1 mm in ≥2 contiguous inferior and/or lateral leads of a standard 12-lead ECG.
3. ER pattern can be diagnosed in the presence of J-point elevation ≥1 mm in ≥2 contiguous inferior and/or lateral leads of a standard 12-lead ECG.

Definition and epidemiology
ER is a common ECG pattern characterized by J-point and ST-segment elevation in two or more contiguous leads. The presence of an ER pattern in the precordial leads has been considered a benign phenomenon, but recently its presence in the inferior and/or lateral leads has been associated with idiopathic ventricular fibrillation (IVF) in case-control studies (ER syndrome). The ER ECG pattern (> 1 mm) in the inferior/lateral leads occurs in 1%–13% of the general population and in 15%–70% of the IVF cases. In the pediatric age group, it is even more prevalent. Male sex is strongly associated with the ER ECG pattern, since more than 70% of the subjects with
ER are men. The ER pattern is more common in young physically active individuals, athletes, and African-Americans.92
There is an increased prevalence of ER reported in Southeast Asians.89

Clinical diagnosis
Patients with the ER pattern on the 12-lead ECG who have been resuscitated from an ECG-documented episode of IVF and/or polymorphic VT are those diagnosed with ER syndrome. Similarly, SCD victims with a negative autopsy with an archived ECG showing the ER pattern are also diagnosed with ER syndrome when evidence of other diagnoses have been excluded.

At this stage of our understanding of ER, there is an unusual dilemma in which the ECG pattern is highly prevalent, the inheritance is not clearly monogenic in most cases, and the genetic substrate is not clearly defined. For this reason, we have chosen not to label family members with the ER pattern as ER syndrome patients, pending a better understanding of their risk. High-risk features including extent of family history of SCD, arrhythmic syncope, and amplitude and morphology of the ER pattern may lead to consideration of a prophylactic ICD in conjunction with review by an expert center with a focus on inherited arrhythmias. Asymptomatic individuals with the ER pattern on ECG with a mutation considered pathogenic for ER as well as family members of a patient diagnosed with ER syndrome who present with a diagnostic ECG may be affected by the disease.

Genetic variants
Familial ER has been reported to have an autosomal dominant inheritance pattern with incomplete penetrance. Two independent population-based studies have also suggested some degree of inheritance of the ER patterns in the general population,93,94 but the familial inheritance of malignant ER patterns has not been clearly demonstrated.93

Clinical manifestations
Life-threatening arrhythmias are often the first and unexpected manifestation of ER syndrome. The majority of population-based studies have shown that subjects with ER in the inferior leads are at a higher risk of all-cause mortality, cardiac mortality, and especially unexpected sudden death,89–91,95 though some exceptions have been reported.96

Risk stratification
The magnitude of the J-point elevation may have prognostic significance. Either slurred or notched J-point elevation ≥0.2 mV is relatively rare in the general population but appears to be associated with an increased risk.91 A horizontal or descending ST-segment elevation following J-point elevation is associated with a worse outcome in the general population.97 This observation has been very helpful in distinguishing IVF patients from matched controls and is a key aid in clinical decision making.98

Management
The clinical implications of the observation of an ER pattern in the ECG of an asymptomatic subject are not clear. The presence of ER is associated with three times the risk of developing VF, but the overall risk is still negligible, considering the rarity of VF in the general population.88,99

Electrical storm is relatively common after ICD implantation in patients with ER syndrome.100,101 Case series evidence supports the acute use of isoproterenol for the suppression of recurrent VF and quinidine for long-term suppression.100,101 Isoproterenol is typically initiated at 1.0 μg/min, targeting a 20% increase in heart rate or an absolute heart rate >90 bpm, titrated to hemodynamic response and suppression of recurrent ventricular arrhythmia.

Screening of family members
No recommendations can be given to screen the families of individuals with an asymptomatic ER pattern.

7. Progressive Cardiac Conduction Disease (PCCD)

Expert Consensus Recommendations on PCCD Diagnosis
1. PCCD is diagnosed in the presence of unexplained progressive conduction abnormalities in young (<50 years) individuals with structurally normal hearts in the absence of skeletal myopathies, especially if there is a family history of PCCD.

Expert Consensus Recommendations on PCCD Therapeutic Interventions
Class I 1. Pacemaker implantation is recommended in patients with a diagnosis of PCCD and the presence of:
   a. Intermittent or permanent third-degree or high-grade atrioventricular (AV) block
   b. Symptomatic Mobitz I or II second-degree AV block.

Class IIa 2. Pacemaker implantation can be useful in patients with a diagnosis of PCCD and the presence of bifascicular block with or without first-degree AV block.
3. ICD implantation can be useful in adult patients diagnosed with PCCD with a mutation in the Lamin A/C gene with left ventricular dysfunction and/or nonsustained VT.
Introduction
PCCD is a heterogeneous disorder of unclear etiology, which can be serious and potentially life-threatening. Its underlying mechanism can be either functional or structural or there can be overlap between these two mechanisms.\textsuperscript{102} The most frequent form of PCCD is a degenerative form called Lenegre-Lev disease. The mechanism of PCCD with structural abnormality is considered as a primary degenerative disease or an exaggerated aging process, with sclerosis principally affecting the conduction tissue.\textsuperscript{103} Aging itself is suggested to play a critical role in PCCD, meaning that at every age, conduction abnormalities are more outspoken than expected based on age alone.

Both familial PCCD with a structurally normal heart (hereby defined as "isolated PCCD") and familial PCCD associated with dilated cardiomyopathy will be discussed.

Genetic variants
The discovery of gene mutations that are causally involved in inherited PCCD is relatively recent.\textsuperscript{102} Common PCCD-associated genes (defined as genes with causative mutation in more than 5% of the affected individuals\textsuperscript{1}) are SCN5A and TRPM4 \textsuperscript{104}for PCCD occurring in the structurally intact heart and LMNA for PCCD associated with heart failure.\textsuperscript{1}

PCCD and structurally normal heart
Mutations in the SCN5A gene cause the majority of familial PCCD and often cause a combined phenotype with BrS.\textsuperscript{103} Subtle structural abnormalities, mainly fibrosis, are present in SCN5A mutation-positive subjects. Recently, mutations in the transient receptor potential channel, subfamily M(elastatin), member 4 (TRPM4) Ca\textsuperscript{2+}-activated channel gene were reported in patients with PCCD\textsuperscript{105} and are estimated to account for a significant portion of inherited forms of right bundle branch block (25%) or AV block (10%).\textsuperscript{1}

PCCD and structurally abnormal heart
When PCCD is accompanied by the presence of concomitant congenital heart disease, mutations in early cardiac transcription factor genes, such as Nkx2.5 or GATA4, are more likely. Mutations in Nkx2.5 or TBX5, genes involved in the regulation of heart development, are associated with structural congenital heart defects, such as septal defects.\textsuperscript{103}

PCCD may also precede the development of dilated cardiomyopathy. Mutations in the LMNA gene encoding Lamin A/C were found to be causally involved in Emery-Dreifus muscular dystrophy as well as in families with dilated cardiomyopathies and severe PCCD without skeletal muscle involvement.\textsuperscript{102,103,106}

Clinical manifestations
PCCD can be seen by a prolonged P-wave duration, PR interval, and QRS widening with axis deviation on the surface ECG, which may progress over time as an age-dependent penetrance. In isolated forms of PCCD, there are typically no extracardiac manifestations. In nonisolated forms of PCCD, congenital heart disease, cardiomyopathy, or extracardiac manifestations may vary from individual to individual and has, among others, an age-dependent onset.\textsuperscript{1}

In patients with mutations in the LMNA gene and PCCD, the AV node and specialized conduction system are progressively replaced by fibrofatty tissue and patients are at risk for premature SCD.\textsuperscript{106,107} In addition to conduction abnormalities, most adult patients with LMNA mutations have AV conduction disturbances and atrial and ventricular arrhythmias.\textsuperscript{108} Heart failure is a common phenotypic feature in families with cardiac manifestations of LMNA disease.\textsuperscript{109,110} The occurrence of tachyarrhythmia and sudden death is expected to be more frequent in PCCD patients that carry loss-of-function SCN5A mutations, a disease entity comparable with SCN5A-associated BrS.\textsuperscript{102}

Diagnosis
The diagnosis of PCCD in an index patient is based on clinical data including history, family history, and 12-lead ECG. The potential presence of congenital heart disease and/or cardiomyopathy must be investigated by 2-D echocardiography or other imaging modalities, such as cardiac magnetic resonance imaging (MRI). Early-onset PCCD in the absence of structural heart disease should prompt consideration of PCCD genetic testing, particularly if there is a positive family history of conduction abnormalities, pacemaker implants, or sudden death.\textsuperscript{1}

(Targeted) genetic testing may be considered as part of the diagnostic evaluation for patients with either isolated PCCD or PCCD with concomitant structural heart disease, especially when there is documentation of a positive family history of PCCD.\textsuperscript{1}

Risk stratification
Screening for underlying cardiovascular manifestations with a resting 12-lead ECG, Holter, or 2-D echocardiogram is recommended, independent of symptom status. Patients with first-degree AV block in association with bifascicular block and symptomatic advanced AV block have a substantial incidence of sudden death. In the presence of permanent or transient third-degree AV block, syncope is associated with an increased incidence of sudden death regardless of EPS results.\textsuperscript{111} Based on this evidence in patients with PCCD diagnosis, pacemaker implant may be indicated even in individuals with bifascicular block and first-degree AV block, thus representing an exception to the recommendation set by international guidelines for patients who have this phenotype in all the other clinical conditions.

Patients with LMNA mutations may experience malignant arrhythmias and SCD despite pacemaker implantation.\textsuperscript{106} ICD therapy is therefore warranted at an early stage; a risk stratification scheme has recently been proposed.\textsuperscript{112}

Management
Once cardiac involvement occurs, particularly with muscular dystrophies, the clinician should maintain a low threshold for investigating symptoms or ECG findings to determine the need for EPS, pacemaker, or ICD implantation.
Asymptomatic family members who are positive for the family’s PCCD-associated mutation should be prospectively followed for the early development of PCCD-related symptoms, deterioration of cardiac conduction, and beginning signs and symptoms of heart failure. In addition, medications with conduction-slowing properties should be restricted and fever, an aggravating trigger in individuals with SCN5A mutations, should be preemptively treated.1

**Screening of family members**

Cascade family screening is useful in families with mutation-positive PCCD. When a clinical diagnosis of PCCD is established in an index case, a careful clinical investigation of first-degree family members is necessary. Genotyping of family relatives is done after mutation identification in the index cases and may be useful to exclude the presence or development of PCCD.

**8. Unexplained Cardiac Arrest: Idiopathic VF**

**Expert Consensus Recommendations on IVF Diagnosis**

1. IVF is diagnosed in a resuscitated cardiac arrest victim, preferably with documentation of VF, in whom known cardiac, respiratory, metabolic, and toxicological etiologies have been excluded through clinical evaluation.

**Expert Consensus Recommendations on IVF Evaluation**

Class IIa 1. Genetic testing in IVF can be useful when there is a suspicion of a specific genetic disease following clinical evaluation of the IVF patient and/or family members.

Class III 2. Genetic screening of a large panel of genes in IVF patients in whom there is no suspicion of an inherited arrhythmogenic disease after clinical evaluation should not be performed.

**Expert Consensus Recommendations on IVF Therapeutic Interventions**

Class I 1. ICD implantation is recommended in patients with a diagnosis of IVF.

Class IIb 2. Antiarrhythmic therapy with quinidine, programmed electrical stimulation guided or empirical, may be considered in patients with a diagnosis of IVF in conjunction with ICD implantation or when ICD implantation is contraindicated or refused.

3. Ablation of Purkinje potentials may be considered in patients with a diagnosis of IVF presenting with uniform morphology premature ventricular contractions in conjunction with ICD implantation or when ICD implantation is contraindicated or refused.

4. If a first-degree relative of an IVF victim presents with unexplained syncope and no identifiable phenotype following thorough investigation, then after careful counseling an ICD implant may be considered.

**Definition**

When individuals survive a cardiac arrest, we are able to investigate and treat them for the underlying cause. The term “idiopathic ventricular fibrillation” (IVF) is used when the cardiac arrest remains unexplained despite this investigation. In 1992, the hypothesis was advanced that concealed inherited forms of arrhythmogenic disorders could underlie IVF.113

**Diagnosis**

IVF is diagnosed by the exclusion through clinical evaluation of known cardiac, respiratory, metabolic, and toxicological etiologies that may lead to cardiac arrest. Ideally, VF should be documented.

**Management**

In IVF, as there is by definition no evidence for pathogenesis, management is empirical and most patients are advised to undergo an ICD implant. Unfortunately, the natural history of IVF is poorly defined and recurrence of arrhythmic events among IVF patients is not consistent among different studies.114–116
Screening of family members
Experience of investigating blood relatives of IVF survivors is limited. A noninvasive diagnostic protocol similar to that utilized in SUDS families may be employed (see Section 9). As with families of SUDS victims, it is reasonable that relatives of IVF survivors who are obligate carriers or have ominous symptoms such as cardiac syncope should be prioritized for evaluation. In families with IVF, young family members may require periodic reassessment even if the initial assessment is normal as young patients may only become cognizant of symptoms at an older age and certain diseases have age-related penetrance. Repeated evaluations should occur if family members become symptomatic or additional suspicious sudden deaths are identified in the family.

9. Unexplained Sudden Cardiac Death: Sudden Unexplained Death Syndrome (SUDS) and Sudden Unexplained Death in Infancy (SUDI)

Expert Consensus Recommendations on SUDS Diagnosis
1. It is recommended that an unexplained sudden death occurring in an individual older than 1 year of age is known as “sudden unexplained death syndrome” (SUDS).
2. It is recommended that a SUDS death with negative pathological and toxicological assessment is termed “sudden arrhythmic death syndrome” (SADS).

Expert Consensus Recommendations on SUDS Evaluation

Class I 1. It is recommended that personal/family history and circumstances of the sudden death are collected for all SUDS victims.
2. It is recommended that all sudden death victims diagnosed with SUDS undergo expert cardiac pathology to rule out the presence of microscopic indicators of structural heart disease.
3. Collection of blood and/or suitable tissue for molecular autopsy/postmortem genetic testing is recommended in all SUDS victims.

Class IIa 4. An arrhythmia syndrome-focused molecular autopsy/postmortem genetic testing can be useful for all SUDS victims.

Expert Consensus Recommendations on SUDS Therapeutic Interventions

Class I 1. Genetic screening of the first-degree relatives of a SUDS victim is recommended whenever a pathogenic mutation in a gene associated with an increased risk of sudden death is identified by molecular autopsy in the SUDS victim.
2. Evaluation of first-degree blood relatives of all SUDS victims with resting ECG with high right ventricular leads, exercise stress testing, and echocardiography is recommended. Assessment of obligate carriers and relatives with a history of palpitations, arrhythmias, or syncope should be prioritized.
3. Follow-up clinical assessment is indicated in young family members of SUDS victims who may manifest symptoms and/or sign of the disease at an older age and in all family members whenever additional SUDS or SUDI events occur.

Class IIa 4. Evaluation of first-degree relatives of SUDS victims with ambulatory and signal-averaged ECGs, cardiac MRI, and provocative testing with Class Ic antiarrhythmic drugs can be useful.

Class IIb 5. Evaluation of first-degree relatives of SUDS victims with epinephrine infusion may be considered.

Expert Consensus Recommendations on SUDI Diagnosis
1. It is recommended that unexplained sudden death occurring in an individual younger than 1 year of age with negative pathological and toxicological assessment is termed “sudden unexplained death in infancy” (SUDI).

Expert Consensus Recommendations on SUDI Evaluation

Class I 1. It is recommended that personal/family history and circumstances of the sudden death are collected for all SUDI victims.
2. Collection of blood and/or suitable tissue for molecular autopsy is recommended in all SUDI victims.

Class IIa 3. An arrhythmia syndrome-focused molecular autopsy/postmortem genetic testing can be useful for all SUDI victims.

Class IIb 4. Sudden death victims diagnosed with SUDI at autopsy may be considered for assessment by an expert cardiac pathologist to rule out the presence of microscopic indicators of structural heart disease.

Expert Consensus Recommendations on SUDI Therapeutic Interventions

Class I 1. Genetic screening of the first-degree relatives of a SUDI victim is recommended whenever a pathogenic mutation in a gene associated with increased risk of sudden death is identified by molecular autopsy in the SUDI victim. Obligate mutation carriers should be prioritized.
Class IIa 2. Evaluation of first-degree relatives of SUDI victims with a family history of inherited heart disease or other SUDS or SUDI deaths with resting ECG and exercise stress testing and additional tests as indicated can be useful. Assessment of first-degree relatives with the history of arrhythmias or syncope should be prioritized.

3. Follow-up clinical assessment can be useful in young family members of SUDI victims with a family history of inherited heart disease or other SUDS or SUDI death who may manifest symptoms and/or signs of the disease at an older age and in all family members whenever additional SUDS or SUDI events occur.

Class IIb 4. Evaluation of first-degree relatives of SUDI victims with resting ECG and exercise stress testing may be considered.

Definitions
An unexplained SCD is a pathological diagnosis of exclusion that covers a number of possible etiologies. A commonly used term is “sudden arrhythmic death syndrome” (SADS) that describes an SCD where an autopsy and toxicology have been undertaken, noncardiac etiologies excluded, and the heart found to be morphologically normal.117,118 Another similar descriptor “sudden infant death syndrome”119 has been termed to describe nonpediatric cases. In Southeast Asia, cases of young male sudden deaths have been attributed to “sudden unexpected or unexplained death syndrome” (SUDS) as well as “sudden unexpected nocturnal death syndrome” (SUNDS). These have, however, been directly related to BrS as an etiology, have been used interchangeably, and do not necessarily imply a thorough pathological evaluation.120 The terms “sudden infant death syndrome” (SIDS) and “sudden unexpected death in infancy” (SUDI) are used in cases younger than 1 year when the cause of death remains unexplained, although SIDS implies a more stringent circumstantial and forensic investigation. These are discussed further below.121

Epidemiology
The incidence of unexplained SCD among the general population aged 4–64 years has been estimated to be up to 1.34/100,000 per annum,118 with 4.1% of the SCD cases in the 16–64 age group being unexplained.119 A recent Irish study reported an incidence of unexplained SCD of 0.76/100,000 year in subjects aged 14–35 years, accounting for 27% of the total incidence of SCD.122

The incidence of unexplained sudden death below 1 year of age (SIDS and SUDI) is well defined and exceeds the incidence of SCD in young adults or in children older than 1 year by an order of magnitude. A recent national study from Ireland revealed a sudden death rate of 1.4/100,000 among children aged 1–4 years compared to 59/100,000 among children younger than 1 year.123 Campaigns to avoid modifiable risk factors (predominantly avoiding the prone sleeping position) have resulted in significant declines in SIDS rates around the world. However, these have plateaued and the current rate of SIDS in the United States is 53/100,000.124

Diagnosis
The diagnosis of an unexplained SCD ideally relies on an autopsy, and toxicological studies are undertaken to exclude noncardiac etiologies. Further pathological evaluation of the heart is then necessary with detailed histopathological examination to exclude clear causes for SCD.125 This may identify structural cardiac genetic disease such as hypertrophic cardiomyopathy that would indicate the need for familial evaluation and the retention of tissue suitable for DNA extraction and targeted genetic testing. If the death remains unexplained, then additional investigations may prove helpful (see Figure 3).

Screening of family members
When first-degree relatives of victims of SADS or premature unexplained sudden death undergo cardiac assessment, up to half of families reveal cardiac genetic diseases such as inherited arrhythmia syndromes or subtle forms of cardiomyopathy.117,126–128 If an autopsy has not been undertaken, then additional etiologies diagnosed in families include cardiomyopathies in general and familial hypercholesterolemia.126,127 The strategy for evaluation is often staged with less invasive investigations first and then more invasive tests if a diagnosis is not made, and it is described in Figure 3.

The investigation of family members of cases of SUDI deaths often occurs on an ad hoc basis, yet there are little data on its yield. Molecular autopsy identifies a lower burden of ion channel disease in SIDS compared to SUDS, and there is a greater likelihood of sporadic genetic disease as a cause of sudden death in infancy. It is therefore likely that the yield of clinical evaluation of first-degree relatives will be significantly lower than in SUDS. Nonetheless, if there is a positive molecular autopsy result, a family history of other cases of SUDI, SUDS, or premature unexplained sudden death or of inherited heart disease, then the yield is likely to be greater and familial evaluation more worthwhile.

10. Inherited Arrhythmia Clinics

Expert Consensus Recommendations on Inherited Arrhythmia Clinics

Class I 3. Patients (probands) and first-degree relatives with a diagnosed or suspected inherited cardiovascular disease as a potential cause of SCD (SUDS/SUDI) should be evaluated in a dedicated clinic with appropriately trained staff
The evaluation and treatment of families suspected of having inherited arrhythmias requires a multidisciplinary team and approach. The presentation is often that of a proband or family member who has experienced a life-threatening arrhythmia, sudden cardiac arrest, or SCD. In the usual circumstances, there are profound and far-reaching medical and psychosocial implications of both presentation of the inherited arrhythmia and genetic testing on patients and families.\textsuperscript{1,2}

Recent evidence suggests that a structured inherited arrhythmia (or inherited cardiovascular disease) clinic improves the likelihood of making a diagnosis in suspected cases of inherited arrhythmias and SCD.\textsuperscript{126,128–132} The promise of an appropriately resourced, structured clinic is

Figure 3  Algorithm to describe the investigative strategy for the identification of inherited heart disease in families that have suffered a SUDS event.
that of a comprehensive evaluation of patients and families, more efficient use of diagnostic testing and therapy and ready access to a broad range of medical, genetics, and psychosocial expertise in managing families afflicted by inherited arrhythmias. An inherited cardiovascular disease clinic is an invaluable resource to patients and families not only at the time of the initial evaluation but also in an ongoing fashion as medical, genetic, and social questions relevant to the inherited heart disease arise.

There are different operational models for inherited arrhythmia clinics; the choice may be determined by the health system or the regulations that exist in a given country. The personnel and workflow in an ideal inherited arrhythmia clinic is illustrated schematically in Figure 4. The key personnel include a clinic coordinator who is responsible for patient intake, collection and collation of medical records, scheduling appointments for patients and family members, and assisting with questions relating to insurance coverage. The physicians are typically a clinical cardiologist/electrophysiologist with expertise in inherited arrhythmias and medical genetics or a medical geneticist with an interest in cardiac arrhythmias partnering with a clinical electrophysiologist. If the inherited arrhythmia clinic is part of a larger program in inherited heart disease, experts in cardiomyopathy will likely be available; otherwise access to such experts is essential.

The increasing complexity and demands of the proper diagnosis and management of patients with inherited cardiovascular disease creates an opportunity for the development of specialized training for clinical electrophysiologists interested in the care of patients with inherited arrhythmias. Such a specialty track would consolidate aspects of care involving indications and interpretation of genetic test results and pharmacological and device therapy.

The management of patients with inherited arrhythmias includes expert judgment regarding the indications, type, and interpretation of genetic testing. In collaboration with a genetic counselor, patients and families should be properly prepared regarding expectations and outcomes of genetic testing. Arguably the most important part of the testing procedure is reviewing the test results and implications with patient and family, with counselor being prepared to discuss the implications for other family members, the meaning of variants of uncertain significance, mosaicism, and issues related to paternity and consanguinity. The genetic counselor is an essential and, in some countries, legally mandated provider in this aspect of the care of patients and families with suspected inherited arrhythmias.
The treatment of patients with inherited arrhythmias may vary from medication therapy and lifestyle modification to device implantation to LCSD. Patients may require invasive EPS and treatment with pacemakers or ICDs.

Patients in an inherited arrhythmia clinic may be survivors of sudden cardiac arrest. The management of the recovery of these patients from their index event may require the expertise of psychologists and psychiatrists, and the intervention of physical and occupational therapists. Moreover, the diagnosis of an inherited disease of any kind, particularly one that carries with it the risk of significant morbidity and premature mortality, is often associated with significant emotional distress that at times will require referral of patients and families.135–141

A structured inherited arrhythmia (or heart disease) clinic provides the platform for optimized multidisciplinary evaluation and management of patients and families with suspected inherited heart disease. The collective efforts of the core staff and access to a variety of experts in related disciplines will result in improved quality of care,128,131,139,142 patient satisfaction,138 and improvement in the appropriate use of diagnostic testing126,130 and therapeutic intervention. The promise of such a clinic structure is lower overall cost and diagnostic testing126,130 and therapeutic intervention of physical and occupational therapists. More-
